

# Content Selection in Deep Learning Models of Summarization

Anonymous EMNLP submission

## Abstract

## 1 Introduction

Content selection is an important sub-task in many natural language generation tasks, where, given a generation goal, the system must determine which information needs to be expressed in output text (Gatt and Krahmer, 2018). In summarization, content selection usually is accomplished through sentence (and less frequently, phrase) extraction. While it is a key component of both extractive and abstractive summarization systems, it is not generally well understood, with frequency and information theoretic measures used as proxies for content salience (Hong and Nenkova, 2014). In this paper, we seek to better understand how deep learning models of summarization perform content selection across a variety of domains. We perform an analysis of several recent sentence extractive neural network architectures, looking particularly at the choice of sentence encoder and sentence extractor design. We compare these recent approaches against a simpler approach based on averaging of word embeddings in order to understand the gains derived from more sophisticated architectures.

[[Kathy: I would find it better to introduce approach here. I've added an extra sentence above. Because your experiments reveal the tidbits below by contrasting past approaches with your simple approach which uses embedding averages]]

Our experiments reveal:

- sentence position bias dominates the learning signal for news though not for other genres. Summary content for news is only slightly degraded when content words are removed.

- Word embedding averaging is as good or better than either RNN or CNN encoders.
- Pre-trained word embeddings are as good or better than learned embeddings in the majority of cases.
- Representation of previously selected summary content does not improve overall summary content.

Taken together, these and other results in the paper suggest that we are overestimating the ability of deep learning models to learn robust and meaningful features for summarization. While we are explicitly studying extractive summarization algorithms here, we think the findings will be relevant to the abstractive summarization community as well. The encoder side architectures are quite similar to typical abstractive models, and fundamentally the model objectives are the same, producing output text with high word overlap to a reference human abstract.

[[Kathy: I think the contributions have to be the results of the study and the actual extractors. I've reworded. You may want to add these contributions once the domain adaptation part done. ]] The contributions of this paper are the following:

1. An empirical study of extractive content selection in deep learning algorithms for text summarization across news, personal narratives, meetings, and medical journal domains using both automatic and manual evaluation revealing ....
2. Two simple sentence extractor models whose performance is on par with more complex models.

## 2 Related Work

[[Kathy: Might want to indicate that this is not recent.]] Pre-neural network approaches to single document summarization are often formulated as graph-based ranking problems, where sentences are nodes in a graph and edges are determined by pairwise similarity of bag-of-words (BOW) representations (Erkan and Radev, 2004; Mihalcea and Tarau, 2005). More recently Wan (2010) jointly performed single and multi-document summarization in this framework. Generally, this line of work does not learn sentence representations for computing the underlying graph structures, which is the focus of this paper.

An notable exception is that of (Yasunaga et al., 2017) who learns a graph-convolutional network for multi-document summarization. However, they do not extensively study the choice of sentence encoder, focusing more on the importance of the graph structure which is orthogonal to this work.

[[Kathy: Again, you need to signal that this was earlier work. Not really sure you need this paragraph. Doesn't seem very relevant.]] To the extent that learning based approaches have been applied to summarization prior to the use of neural networks, typically they have involved learning ngram feature weights in linear models along with other non-lexical word or structure features (Berg-Kirkpatrick et al., 2011; Sipos et al., 2012; Durrett et al., 2016).

The introduction of the CNN-DailyMail corpus by (Hermann et al., 2015) allowed for the application of large-scale training of deep learning models for summarization, [[Kathy: This is a wordy way to cite. Couldn't you just put the citation after the appropriate pphrase? If you say "by" then I think you have to use ?o that the name appears in the text.]] initially by (Cheng and Lapata, 2016) who present both a sentence and word extractive model of single document summarization. The sentence extractive model uses a word level convolutional neural network (CNN) to encode sentences and a sentence level sequence-to-sequence model to predict which sentences to include in the summary. Nallapati et al. (2017) proposed a different model using word-level bidirectional recurrent neural networks (RNNs) along with a sentence level bidirectional RNN for predicting which sentences should be extracted. Additionally, the sentence extractor creates represen-

tations of the whole document and computes separate scores for salience, novelty, and location.

Since these two models are very different in design, it is unclear what model choices are most important for indentifying summary content in the input document. We use the sentence extractor designs of (Cheng and Lapata, 2016) and (Nallapati et al., 2017) as points of comparison in our experiments (Section ??).

All of the previous works focused on news summarization. To further understand the content selection process, we also explore other domains of summarization. In particular, we explore summarization of personal narratives shared on the website Reddit (Ouyang et al., 2017), workplace meeting summarization (Carletta et al., 2005), and medical journal article summarization (Mishra et al., 2014). While most work on these summarization tasks often exploit features relevant to the domain, e.g. speaker identification in meeting summarization (Gillick et al., 2009), [[Kathy: "eschew" has a negative connotation. Implies you think this is the wrong way to go. I don't think you mean that. I think what you really mean is you want to understand whether general neural net features can control content selection without adding domain specific features. People will otherwise argue with "understand generally" since such features may play an important role.]] we eschew such features in this work in order to understand generally how content selection is learned.

As is also the case in other NLP tasks, it is not immediately obvious how a deep learning model is making its predictions, or what correlations are being exploited. There is a concerning and growing list of papers that find models functioning as mere nearest neighbors search (Chen et al., 2016), exploiting annotator artifacts (Gururangan et al., 2018), or open to fairly trivial adversarial exploitation (Jia and Liang, 2017). These lines of research are critical for finding model shortcomings, and over time, guiding improvements in technique. Unfortunately, to the best of our knowledge, there has been no such undertaking for the summarization task.

## 3 Problem Definition

[[Kathy: Overall, this quite a short section. Is it needed? Or should it be morged somewhere else?]]

[[Kathy: Again, I think you have to state that the unit for extraction is the sentence.]] The goal of extractive text summarization is to select a subset of a document’s text to use as a summary, i.e. a short gist or excerpt of the central content. Typically, we impose a budget on the length of the summary in either words or bytes.

We evaluate summary quality using ROUGE (Lin, 2004) which measures the ngram overlap of our predicted extract summary with one or more human abstracts. We use ROUGE-2 recall (i.e. bigram recall) as our main evaluation metric (ROUGE-1 and ROUGE-LCS trend similarity to ROUGE-2 in our experiments). We also evaluate using METEOR (Denkowski and Lavie, 2014) which measures precision and recall of reference words, while allowing for more complicated word matchings (e.g. via synonymy or morphology).

In this paper, we model this task as a sequence tagging problem, i.e. given a document containing  $d$  sentences  $s_1, \dots, s_d$  we want to predict a corresponding label sequence  $y_1, \dots, y_d \in \{0, 1\}^d$  where  $y_i = 1$  indicates the  $i$ -th sentence is to be included in the summary.

## 4 Models and Methods

[[Hal: i’m having a hard time understanding what’s new and what’s prior work here.]]

For a typical deep learning model of extractive summarization there are two main design decisions: *i*) the choice of *sentence encoder* which maps each sentence  $s_i$  to an embedding  $h_i \in \mathcal{R}^d$ , and *ii*) the choice of *sentence extractor* which maps a sequence of sentence embeddings  $h = h_1, \dots, h_n$  to a sequence of extraction decisions  $y = y_1, \dots, y_n$ . The sentence extractor is then a discriminative classifier  $p(y|h)$ .

We study three architectures for the sentence encoders, namely, embedding averaging, RNNs, and CNNs. We also propose two simple models for the sentence extractor and compare to the previously proposed extractors of Cheng and Lapata (2016) and Nallapati et al. (2017). The prior works differ significantly but make the same semi-Markovian factorization of the extraction decisions, i.e.  $p(y|h) = \prod_{i=1}^n p(y_i|y_{<i}, h)$ , where each prediction  $y_i$  is dependent on all previous  $y_j$  for all  $j < i$ . By contrast, our extractors make a stronger conditional independence assumption  $p(y|h) = \prod_{i=1}^n p(y_i|h)$ , essentially making independent predictions conditioned on  $h$ . In theory,

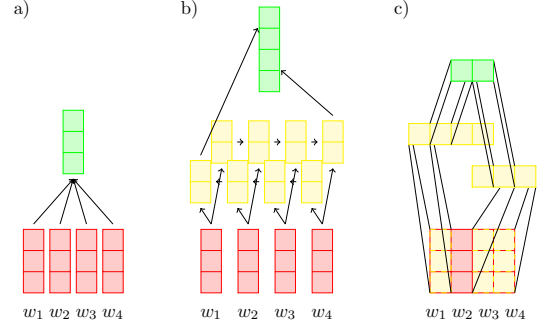

Figure 1: Sentence encoder architectures: a) averaging encoder, b) RNN encoder c) CNN encoder. Red indicates word embeddings, yellow indicates RNN hidden states or convolutional activations, and green indicates the sentence embedding that is passed to the extractor module.

our models should perform worse because of this, however, as we later show, this is not the case empirically.

### 4.1 Sentence Encoders

We treat each sentence  $s = w_1, \dots, w_{|s|}$  as a sequence of word embeddings, where  $w_i \in \mathcal{R}^{n'}$  are word embeddings and  $|s|$  is the total number of words in the sentence. We experiment with three architectures for mapping sequences of word embeddings to a fixed length vector: averaging, RNNs, and CNNs. See Figure 1 for a diagram of the three encoders.

**Averaging Encoder** The averaging encoder (AVG) is the simplest method and has the added benefit of being parameter free. Under the averaging encoder, a sentence embedding  $h = \frac{1}{|s|} \sum_{i=1}^{|s|} w_i$  is simply the average of its word embeddings.

**RNN Encoder** The RNN sentence encoder uses the concatenation of the final output states of a forward and backward RNN over the sentence’s word embeddings. We use a Gated Recurrent Unit (GRU) for the RNN cell, since it has fewer parameters than the equivalent LSTM but with similar performance (Chung et al., 2014). Under the RNN encoder, a sentence embedding is defined as  $h = [\vec{h}_{|s|}; \overleftarrow{h}_1]$  where

$$\vec{h}_0 = \mathbf{0}; \quad \vec{h}_i = \overrightarrow{\text{GRU}}(w_i, \vec{h}_{i-1}) \quad (1)$$

$$\overleftarrow{h}_{|s|+1} = \mathbf{0}; \quad \overleftarrow{h}_i = \overleftarrow{\text{GRU}}(w_i, \overleftarrow{h}_{i+1}), \quad (2)$$

and  $\overrightarrow{\text{GRU}}$  and  $\overleftarrow{\text{GRU}}$  indicate the forward and backward GRUs respectively, each with separate parameters.

**CNN Encoder** The *CNN* sentence encoder uses a series of convolutional feature maps to encode each sentence. This encoder is similar to the convolutional architecture of (Kim, 2014) used for text classification tasks and performs a series of “one-dimensional” convolutions over word embeddings. The *CNN* encoder has hyperparameters associated with the window sizes  $K \subset \mathcal{N}$  of the convolutional filter (i.e. the number of words associated with each convolution) and the number of feature maps  $M$  associated with each filter (i.e. the output dimension of each convolution). The *CNN* sentence embedding  $h$  is computed as follows:

$$a_i^{(m,k)} = b^{(m,k)} + \sum_{j=1}^k W_j^{(m,k)} \cdot w_{i+j-1} \quad (3)$$

$$h^{(m,k)} = \max_{i \in 1, \dots, |s|-k+1} \text{ReLU}(a_i^{(m,k)}) \quad (4)$$

$$h = [h^{(m,k)} | m \in \{1, \dots, M\}, k \in K] \quad (5)$$

where  $b^{(m,k)} \in \mathcal{R}$  and  $W^{(m,k)} \in \mathcal{R}^{k \times n'}$  are learned bias and filter weight parameters respectively, and  $\text{ReLU}(x) = \max(0, x)$  is the rectified linear unit activation.

## 4.2 Sentence Extractors

Given a sequence of sentence embeddings  $h = h_1, \dots, h_n$  produced by a sentence encoder, a sentence extractor defines a conditional distribution  $p(y|h)$  over the corresponding sentence extraction variables.

We first propose two simple extractor models based on bidirectional RNN and sequence-to-sequence with attention architectures, which we refer to as the RNN and Seq2Seq extractors respectively.

Next we define the extractor models of Cheng & Lapata, and Nallapati et al., whose models we refer to as the Cheng & Lapata and SummaRunner extractors respectively. See Figure 2 for a diagram of the four sentence extractor architectures.

**RNN Extractor** Our first proposed model is a very simple bidirectional RNN based tagging model. As in the RNN sentence encoder we use a GRU cell. The the forward and backward outputs of each sentence are passed through a multi-layer perceptron with a logisitc sigmoid output (denoted

by  $\sigma$ ) to predict the probability of extracting each sentence:

$$\vec{z}_0 = \mathbf{0}; \quad \vec{z}_i = \overrightarrow{\text{GRU}}(h_i, \vec{z}_{i-1}) \quad (6)$$

$$\overleftarrow{z}_{n+1} = \mathbf{0}; \quad \overleftarrow{z}_i = \overleftarrow{\text{GRU}}(h_i, \overleftarrow{z}_{i+1}) \quad (7)$$

$$a_i = \text{ReLU}(U \cdot [\vec{z}_i; \overleftarrow{z}_i] + u) \quad (8)$$

$$p(y_i = 1|h) = \sigma(V \cdot a_i + v) \quad (9)$$

where  $\overrightarrow{\text{GRU}}$  and  $\overleftarrow{\text{GRU}}$  indicate the forward and backward GRUs respectively, and each have separate learned parameters;  $U, V$  and  $u, v$  are learned weight and bias parameters.

**Seq2Seq Extractor** One shortcoming of the RNN extractor is that long range information from one end of the document may not easily be able to effect extraction probabilities of sentences at the other end. Our second proposed model, the Seq2Seq extractor mitigates this problem with an attention mechanism commonly used for neural machine translation (Bahdanau et al., 2014) and abstractive summarization (See et al., 2017). The sentence embeddings are first encoded by a bidirectional GRU. A separate decoder GRU transforms each sentence into a query vector which attends to the encoder output. The attention weighted encoder output and the decoder GRU output are concatenated and fed into a multi-layer perceptron to compute the extraction probability. Formally we have:

$$\vec{z}_0 = \mathbf{0}; \quad \vec{z}_i = \overrightarrow{\text{GRU}}_{enc}(h_i, \vec{z}_{i-1}) \quad (10)$$

$$\overleftarrow{z}_{n+1} = \mathbf{0}; \quad \overleftarrow{z}_i = \overleftarrow{\text{GRU}}_{enc}(h_i, \overleftarrow{z}_{i+1}) \quad (11)$$

$$\vec{q}_i = \overrightarrow{\text{GRU}}_{dec}(h_i, \vec{q}_{i-1}) \quad (12)$$

$$\overleftarrow{q}_i = \overleftarrow{\text{GRU}}_{dec}(h_i, \overleftarrow{q}_{i+1}) \quad (13)$$

$$q_i = [\vec{q}_i; \overleftarrow{q}_i], \quad z_i = [\vec{z}_i; \overleftarrow{z}_i] \quad (14)$$

$$\alpha_{i,j} = \frac{\exp(q_i \cdot z_j)}{\sum_{j=1}^n \exp(q_i \cdot z_j)}, \quad \bar{z}_i = \sum_{j=1}^n \alpha_{i,j} z_j \quad (15)$$

$$a_i = \text{ReLU}(U \cdot [\bar{z}_i; q_i] + u) \quad (16)$$

$$p(y_i = 1|h) = \sigma(V \cdot a_i + v). \quad (17)$$

The final outputs of each encoder direction are passed to the first decoder steps; additionally, the first step of the decoder GRUs are learned “begin decoding” vectors  $\vec{q}_0$  and  $\overleftarrow{q}_0$  (see Figure 2.b).

Figure 2: Sentence extractor architectures: a) RNN, b) Seq2Seq, c) C&amp;L, and d) SR.

Each GRU has separate learned parameters;  $U, V$  and  $u, v$  are learned weight and bias parameters.

**Cheng & Lapata Extractor** We compare the previously proposed architectures to the sentence extractor model of (Cheng and Lapata, 2016). The basic architecture is a unidirectional sequence-to-sequence model defined as follows:

$$z_0 = \mathbf{0}; \quad z_i = \text{GRU}_{enc}(h_i, z_{i-1}) \quad (18)$$

$$q_1 = \text{GRU}_{dec}(h_*, z_n) \quad (19)$$

$$q_i = \text{GRU}_{dec}(p_{i-1} \cdot h_{i-1}, q_{i-1}) \quad (20)$$

$$a_i = \text{ReLU}(U \cdot [z_i; q_i] + u) \quad (21)$$

$$p_i = p(y_i = 1 | y_{<i}, h) = \sigma(V \cdot a_i + v) \quad (22)$$

where  $h_*$  is a learned “begin decoding” sentence embedding (see Figure 2.c). Each GRU has separate learned parameters;  $U, V$  and  $u, v$  are learned weight and bias parameters. Note in Equation 20 that the decoder side GRU input is the sentence embedding from the previous time step weighted by its probability of extraction ( $p_{i-1}$ ) from the previous step, inducing dependence of each output  $y_i$  on all previous outputs  $y_{<i}$ .

Note that in the original paper, the Cheng & Lapata extractor was paired with a CNN sentence encoder, but in this work we experiment with a variety of sentence encoders.

**SummaRunner Extractor** Our second baseline, which we refer to as the SummaRunner extractor is taken from (Nallapati et al., 2017). Like the RNN extractor it starts with a bidirectional GRU over the sentence embeddings

$$\vec{z}_0 = \mathbf{0}; \quad \vec{z}_i = \overrightarrow{\text{GRU}}(h_i, \vec{z}_{i-1}) \quad (23)$$

$$\overleftarrow{z}_{n+1} = \mathbf{0}; \quad \overleftarrow{z}_i = \overleftarrow{\text{GRU}}(h_i, \overleftarrow{z}_{i+1}), \quad (24)$$

It then creates a representation of the whole document  $q$  by passing the averaged GRU output states through a fully connected layer:

$$q = \tanh\left(b_q + W_q \frac{1}{n} \sum_{i=1}^n [\vec{z}_i; \overleftarrow{z}_i]\right) \quad (25)$$

A concatenation of the GRU outputs at each step are passed through a separate fully connected layer to create a sentence representation  $z_i$ , where

$$z_i = \text{ReLU}(b_z + W_z [\vec{z}_i; \overleftarrow{z}_i]). \quad (26)$$

The extraction probability is then determined by contributions from five sources:

$$\text{content} \quad a_i^{(con)} = W^{(con)} z_i, \quad (27)$$

$$\text{salience} \quad a_i^{(sal)} = z_i^T W^{(sal)} q, \quad (28)$$

$$\text{novelty} \quad a_i^{(nov)} = -z_i^T W^{(nov)} \tanh(g_i), \quad (29)$$

$$\text{position} \quad a_i^{(pos)} = W^{(pos)} l_i, \quad (30)$$

$$\text{quartile} \quad a_i^{(qrt)} = W^{(qrt)} r_i, \quad (31)$$

where  $l_i$  and  $r_i$  are embeddings associated with the  $i$ -th sentence position and the quarter of the document containing sentence  $i$  respectively. In Equation 29,  $g_i$  is an iterative summary representation computed as the sum of the previous  $z_{<i}$  weighted by their extraction probabilities,

$$g_i = \sum_{j=1}^{i-1} p(y_j = 1 | y_{<j}, h) \cdot z_j. \quad (32)$$

Note that the presence of this term induces dependence of each  $y_i$  to all  $y_{<i}$  similarly to the Cheng & Lapata extractor.

The final extraction probability is the logistic sigmoid of the sum of these terms plus a bias,

$$p(y_i = 1|y_{<i}, h) = \sigma \left( \frac{a_i^{(con)} + a_i^{(sal)} + a_i^{(nov)}}{+a_i^{(pos)} + a_i^{(qrt)} + b} \right) \quad (33)$$

The weight matrices  $W_q$ ,  $W_z$ ,  $W^{(con)}$ ,  $W^{(sal)}$ ,  $W^{(nov)}$ ,  $W^{(pos)}$ ,  $W^{(qrt)}$  and bias terms  $b_q$ ,  $b_z$ , and  $b$  are learned parameters; The GRUs have separate learned parameters.

Note that in the original paper, the SummaRuner extractor was paired with an *RNN* sentence encoder, but in this work we experiment with a variety of sentence encoders.

## 5 Datasets

We perform our experiments across six corpora from varying domains to understand how different biases with each domain can effect content selection. The corpora come from the news domain (CNN-DailyMail, New York Times, DUC), personal narratives domain (Reddit), workplace meetings (AMI), and medical journal articles (PubMed).

**CNN-DailyMail** We use the preprocessing and training, validation, and test splits of (See et al., 2017) yielding 287,113/13,368/11,490 documents respectively, each with one reference abstract. This corpus is a mix of news on different topics including politics, sports, and celebrity news.

**New York Times** The New York Times (NYT) corpus (Sandhaus, 2008) contains two types of abstracts for a subset of its articles. The first summary is an abstract produced by an archival librarian and the second is an online teaser meant to elicit a viewer on the webpage to click to read more. From this collection we take all articles that have a combined summary length of at least 100 words. This collection includes both straight newswire as well as opinion and long-form journalism. We create training, validation, test splits by partitioning on dates; we use the year 2005 as the validation data, with training and test partitions including documents before and after 2005 respectively, yielding 44,382/5,523/6,495 documents.

**DUC** We use the single document summarization data from the 2001 and 2002 Document Understanding Conferences (DUC) (Over and

Liggett, 2002). We split the 2001 data into training and validation splits and reserve the 2002 data for testing, resulting in 516/91/657 documents for training, validation, and test respectively. The test set has two or three human abstracts roughly 100 words in length per articles.

**AMI** The AMI corpus (Carletta et al., 2005) is collection real and staged office meetings annotated with text transcriptions, along with abstractive summaries. We use the proscribed splits to get 98/19/20 training, validation, and test examples with one human abstract summary per meeting. We ignore any speaker information since we are primarily interested in studying content selection in a domain agnostic way. The summaries are about 290 words long on average and so we target this length for summary generation.

**Reddit** (Ouyang et al., 2017) collected a corpus a personal stories shared on Reddit<sup>1</sup> along with multiple extractive and abstractive summaries. These stories are relatively short compared to the other corpora with an average sentence length of ??. We created our own train, validation, and test splits resulting in 404/24/48 documents respectively.

**PubMed** We created a corpus of 25,000 randomly samples medical journal articles from the PubMed Open Access Subset<sup>2</sup>. We only included articles if they were at least 1000 words long and had an abstract of at least 50 words in length. We used 21250/1250/2500 document for training, validation, test respectively. We used the article abstracts as the ground truth human summaries.

## 6 Experiments

We train all models to minimize the weighted negative log likelihood

$$\mathcal{L} = - \sum_{s, y \in \mathcal{D}} \sum_{i=1}^n \omega(y_i) \log p(y_i | y_{<i}, \text{enc}(s))$$

over the training data  $\mathcal{D}$  using stochastic gradient descent with the ADAM optimizer (Kingma and Ba, 2014). The term

$$\omega(y_i) = \begin{cases} \frac{\sum_{y_j} \mathbb{1}\{y_j=0\}}{\sum_{y_j} \mathbb{1}\{y_j=1\}} & \text{if } y_i = 1 \\ 1 & \text{otherwise} \end{cases}$$

Table 1: ROUGE 2 recall results across all sentence encoder/extractor pairs. All results are averaged over five random initializations. Results that are statistically indistinguishable from the best system are shown in bold face.

upweights positive examples proportionally to the ratio of negative to positive examples in the training data in order to compensate for the sparsity of the positive class. We use a learning rate of .0001 and a dropout rate of .25 for all dropout layers. We also employ gradient clipping ( $-5 < \nabla_{\theta} < 5$ ). We train for a maximum of 30 epochs and the best model is selected with early stopping on the validation set according to ROUGE-2 recall. All experiments are repeated with five random initializations. Weight matrix parameters are initialized using Xavier initialization with the normal distribution (Glorot and Bengio, 2010) and bias terms are set to 0. Unless specified, word embeddings are initialized using pretrained GloVe embeddings (Pennington et al., 2014) and we do not update them during training. Unknown words are mapped to a zero embedding. We use a batch size of 32 for all datasets except AMI and PubMed for which we use sizes two and four respectively. For the Cheng & Lapata model, we train for half of the maximum epochs with teacher forcing, i.e. we set  $p_i = 1$  if  $y_i = 1$  in the gold data and 0 otherwise when computing the decoder input  $p_i \cdot h_i$ ; we revert to the true model probability during the second half training.

## 6.1 Ground Truth Extract Summaries

Since we do not typically have ground truth extract summaries from which to create the labels  $y_i$ , we construct gold label sequences by greedily optimizing ROUGE-1. Starting with an empty summary  $S = \emptyset$ , we add the sentence  $\hat{s} =$

$\arg \max_{s \in \{s_1, \dots, s_d\}, s \notin S} \text{ROUGE-1}(S \cup s)$  to  $S$  stopping when the ROUGE-1 score no longer increases or the length budget is reached. We choose to optimize for ROUGE-1 rather than ROUGE-2 similarly to other optimization based approaches to summarization (Durrett et al., 2016; Sipos et al., 2012; Nallapati et al., 2017) which found this to be the easier optimization target.

**Extractor/Encoder Comparisons** In our main experiment, we compare our proposed sentence extractors, RNN and Seq2Seq, to those of Cheng & Lapata and SummaRunner. We test all possible sentence extractor/encoder pairs across all the datasets described in Section 5.

In most cases, the averaging encoder performance was as good or better than the RNN and CNN encoders, we use only the averaging encoder for the remainder of the experiments.

**Word Embedding Learning** To further understand how word embeddings can effect model performance we also compared extractors when embeddings are updated during training. Both fixed and learned embedding variants are initialized with GloVe embeddings. When learning embeddings, words occurring three or fewer times in the training data are mapped to a learned unknown token.

**POS Tag Ablation** Additionally, we ran ablation experiments using part-of-speech (POS) tags. All datasets were automatically tagged using the

SpaCy POS tagger<sup>3</sup>. We experimented with selectively removing

- nouns (NOUN and PROPN tags),
- verbs (VERB, PART, and AUX tags),
- adjectives/adverbs (ADJ and ADV tags),
- numerical expressions (NUM and SYM tags), and
- miscellaneous words (ADP, CONJ, CCONJ, DET, INTJ, and SCONJ tags)

from each sentence. The embeddings of removed words were replaced with a zero vector, preserving the order and position of the non-ablated words in the sentence.

**Document Shuffling** In examining the outputs of the models, we found most of the selected sentences in the news domain came from the lead paragraph of the document. This is despite the fact that there is a long tail of sentence extractions from later in the document in the ground truth extract summaries. Because this lead bias is so strong, it is questionable whether the models are learning to identify important content or just find the start of the document. We perform a series of sentence order experiments where each document’s sentences are randomly shuffled during training. We then evaluate each model performance on the unshuffled test data, comparing to the original unshuffled models.

## 7 Results

The results of our main experiment comparing the different extractors/encoders are shown in Table 1. Overall, we find no major advantage when using the CNN and RNN sentence encoders. The best performing encoder/extractor pair uses the averaging encoder (4 out of 5 datasets) or the differences are not statistically significant. When only comparing within the same extractor choice, the averaging encoder is the better choice in 14 of 20 cases.

When looking at extractors, the Seq2Seq extractor is either part of the best performing system (2 out of 5 datasets) or is not statistically distinguishable from the best extractor.

Overall, on the news domain, the differences are quite small with the differences between worst

and best systems on the CNN/DM dataset spanning only .56 of a ROUGE point. While there is more performance variability in the non-news domains, there is less distinction among systems: all systems are statistically indistinguishable from the best system on Reddit and every extractor has at least one configuration that is indistinguishable from the best system on the AMI corpus.

**Word Embedding Learning** Table 2 shows ROUGE recall when using fixed or updated word embeddings. **In all but one case, fixed embeddings are as good or better than the learned embeddings.** This is a somewhat surprising finding, and suggests that our models cannot extract much generalizable learning signal from the content than what is already present from initialization. The AMI corpus is an exception here where learning does lead to small performance boosts, however, only in the Seq2Seq extractor is this difference significant. The language of this corpus is quite different from the data that the GloVe embeddings were trained on and so it makes sense that there would be more benefit to learning word representations; one explanation for only seeing modest improvements is purely the small size of the dataset (**NOTE TO CK – expect learning to help on pubmed**).

**POS Ablation** Table 3 shows the results of the POS tag ablation experiments. While removing any word class from the representation generally hurts performance (with statistical significance) on the news domains, the absolute values of the differences are quite small (.18 on CNN/DM, .41 on NYT, .3 on DUC) suggesting that the model’s predictions are not overly dependent on any particular word types. On the non-news datasets, the ablations have a larger effect (max differences are 1.89 on Reddit, 2.56 on AMI). Removing the content words leads to the largest drop on AMI. Removing adjectives and adverbs leads to the largest drop on Reddit, suggesting the intensifiers and descriptive words are useful for identifying important content in personal narratives. Curiously, removing the miscellaneous POS class yields a significant improvement on DUC 2002 and AMI.

**Document Shuffling** Table 4 shows the results of our shuffling experiments. The newswire domain suffer a significant drop in performance when the document order is shuffled. **By comparison, there is no significant difference between the shuffled and in-order models on the Reddit domain, and actually improves performance on the**

<sup>3</sup><https://github.com/explosion/spaCy>

AMI.

## 8 Discussion

The lack of distinction amongst sentence encoders is interesting because it echoes findings in the generic sentence embedding literature where word embedding averaging is frustratingly difficult to outperform (Wieting et al., 2015; Arora et al., 2016; Wieting and Gimpel, 2017).

## 9 Conclusion

We have presented an empirical study of deep learning based content selection algorithms for summarization. Our findings suggest more work is needed on sentence representation.
